Grant Agreement Number: 285121

Project acronym: MAINLINE

Project title: MAINTenance, renewaL and Improvement of rail transport iNfrastructure to reduce Economic and environmental impacts

Funding Scheme: Collaborative project

Date of latest version of Annex I against which the assessment will be made: 8 June 2014

Period covered From 01 October 2011 to 30 September 2014

Name of the scientific representative of the project's co-ordinator, Title and Organisation:

Mr. Björn PAULSSON, Senior Advisor, UIC (International Union of Railways) / TRAFIKVERKET

Tel: +46 10 123 52 04 – Mob: +46 70 72 45 620

E-mail: bjorn.paulsson@trafikverket.se

1. Final Publishable Summary Report

1.1 Executive Summary

The MAINLINE project, funded under the Seventh Framework Programme of the European Commission, has been prepared under the auspices of the International Railways Union (UIC) to address work programme topic SST.2011.5.2-6. “Cost-effective improvement of rail transport infrastructure”. This 3-year project brought together infrastructure managers and railway undertakings from across Europe, contractors and consulting engineers with a wide experience of improving existing rail transport infrastructure and academics widely respected for their understanding of the issues related to elderly infrastructure.

Growth in demand for rail transportation across Europe is predicted to continue. Much of this growth will have to be accommodated on existing lines that contain elderly infrastructure and will increase both the rate of deterioration of these assets and the need for shorter line closures for maintenance or renewal interventions. However, interventions on elderly infrastructure will also need to take account of the need for lower economic and environmental impacts.

MAINLINE proposed to address all these issues through a series of linked activities that targeted at least €300m per year savings across Europe coupled with a reduced environmental footprint, principally measured in terms of embodied carbon, and other environmental benefits: both life extension and replacement techniques have been studied, as well as degradation models and monitoring.

Balancing the economic and environmental costs generated by the maintenance and renewal of existing infrastructure is far more difficult than it is when building new, especially as it is necessary to minimise the risks to the continued safe operation of the transport network. It is also necessary to balance the natural desire for lower first cost solutions, particularly in the current economic downturn, with the real need to achieve the lowest life cycle cost.

The development of a tool to assist railway administrations to balance these various considerations was the principal objective of the MAINLINE project and the work plan was arranged to ensure that this objective was kept central to the project activities. A key feature of the MAINLINE project was not only the development of such a tool, but also the provision of sufficient validation to enable infrastructure managers to adopt it with confidence. Although the LCAT is focused on metallic bridges, plain track and soil cuttings, MAINLINE has studied other assets such as switches & crossings (S&C) and tunnels.

Thanks to the MAINLINE project, Infrastructure Managers will be better able to analyse and plan their infrastructure maintenance programs, since they will have access to new and improved renewal/ strengthening/refurbishment solutions and an evaluation tool that is capable of accurately comparing cost-efficiency on a whole life basis, taking into account operational, environmental and economic criteria.

The project has quantified the needs arising from emerging freight and passenger demands across Europe with special emphasis being placed on Eastern Europe in order to develop client options and preferred solutions that are affordable, whilst maintaining operational safety.

MAINLINE has drawn on the considerable progress made within recently completed European projects regarding the maintenance and renewal of both track and switches & crossings (INNOTRACK) and bridges (Sustainable Bridges), and has also benefited from partners’ expertise in other infrastructure networks.
1.2 Description of the Project Context and Objectives

The demand for rail transportation across Europe is continuously increasing, and growth is predicted to continue into the future. Midterm projections by the EC, COM (2006), expect rail freight and passenger traffic to rise by around 13% and 19% respectively between 2000 and 2020. Whilst some of this growth will be met, particularly in Western Europe by the building of new high speed lines, much of it will have to be accommodated on existing lines which contain some of the oldest transportation infrastructure now in regular use for long distance journeys. For instance it is estimated that some 35% of the railway bridges in Europe are in excess of 100 years and major earthworks (cuttings and embankments) and tunnels date back to the original construction of the route, possibly in excess of 150 years.

The predicted increase in traffic on existing elderly rail infrastructure across Europe will result in increased rates of degradation for the civil engineering and track assets utilised, which will then need to be maintained, and when necessary, replaced, in as short time as possible so that disruption to the flow of freight and passengers is kept to a minimum. However, in order to maintain rail’s competitiveness, faster maintenance and renewal activities will have to be undertaken without any increase in real costs and preferably at lower cost than traditionally has been the case. In addition, the increasing worldwide importance of environmental considerations in infrastructure maintenance and renewal activities, particularly those related to climate change (generally expressed in terms of carbon emissions) means that new techniques will have to be rigorously evaluated to ensure that their environmental cost is also kept to a minimum. The possibility of safely extending the life of existing infrastructure in order to deal with both historic under investment in railway networks and short term financial constraints can also provide great savings in environmental impact as it will postpone the need for the construction of new assets.

The main objective of the MAINLINE project was to develop methods and tools that will contribute to a more cost efficient and effective improvement of European railway infrastructure based on whole life considerations. In view of the scale of renewal dictated by conventional methods in the future, the specific objectives of the project were to:

- Apply new technologies to extend the life of elderly infrastructure,
- Improve degradation and structural models to develop more realistic life cycle cost and safety models,
- Investigate new construction methods for the replacement of obsolete infrastructure,
- Investigate monitoring techniques to complement or replace existing techniques,
- Develop management tools to assess whole life environmental and economic impact.

Project benefits have also been derived from keeping existing infrastructure safely in service through the application of technologies and interventions based on life cycle considerations. Although MAINLINE has focused on certain asset types, the management tools developed are also applicable across a broader asset base.

The overall structure and interactions of the Work Packages (WPs) are demonstrated in the following figure.

---

1.3 Description of the main S&T Results/Foregrounds

1.3.1 Life extension of elderly infrastructure

The main objective of this life extension work package was to apply new technologies to extend the life of elderly infrastructure. This can be subdivided as follows:

- to explore and evaluate new technologies to extend the life length,
- to develop new more accurate assessment methods to determine if and when the life can be extended without any interventions (as e.g. strengthening),
- to further develop new technologies that can reduce life cycle costs for repair and strengthen and minimize the necessary traffic interruption,
- to develop a guideline for the application of new technologies to extend the life length,
- to transfer existing knowledge of new technologies to Eastern Europe and developing economies.
- to deliver input regarding data to the development of life cycle cost models and other decision support systems. This includes describing the cost and effect on the environment of applied technologies.

In line with the objectives, the following results have been achieved:

1. New technologies and novel methods to extend the service life of bridges, tunnels, track and earthworks have been explored and described in a guideline (D1.4).
   - For bridges this has included describing the use of both retrospective post tensioning and the application of fibre reinforced polymer (FRP) plates to increase carrying capacity. A cost saving of between 75% and 85% compared with the alternative solution of replacement was achieved for one Swedish case study.
described in detail in Appendix B to report D1.3 and illustrated in Figure 1.2 where retrospective post tensioning permitted an increase in permissible axle load from 250kN to 300kN.

Figure 1-2 The Swedish bridge strengthened with retrospective post tensioning

- For tunnels the use of techniques such as sprayed concrete replacement linings and both traditional and proprietary roof support systems (shown in Figure 1.3) to maintain safety are described in case studies in Appendix C to report D1.3.

Figure 1-3 Traditional and proprietary tunnel roof support systems

- For track, life extension by grinding, ballast tamping and cleaning and stone blowing have been examined and recommendations made.
- For earthworks the use of lime columns and vertical drains to maintain safety and reduce future maintenance needs has been described.

2. More accurate assessment methods have been developed to study if and when the life can be extended for bridges, track and earthworks without any interventions.
- For bridges the use of advanced assessment techniques such as direct reliability, the calculation of system safety, redundancy and robustness criteria and consideration of site specific loading, dynamic amplification factors and temperature effects have been described. Sample calculations are included in Appendix A to D1.3. The benefit of finite element (FE) modelling has been demonstrated through the use of a FE model to compare predictions with the
actual results of the test to failure of the Åby River metal truss bridge in northern Sweden, (see Figure 1.4), which is also discussed in detail in Appendix A to D1.3. This work has enabled a number of similar bridges to be kept in service carrying higher axle loads.

- For track the benefit of refined inspection and assessment techniques such as infrastructure mounted video cameras, high speed inspection of switches using lasers, SIM (Switch Inspection Measurement) wagon and in-service track geometry recoding have been explored.
- For earthworks the benefits from the use of slope stability analysis to identify potential future failure sites has been described and the technique used to help populate the LCAT developed by WP5.

![Figure 1-4 The Åby bridge after failure, which was caused by buckling of the top flange of the main truss girders. The failure was quite ductile and the bridge could continue to carry a high load after failure, as predicted by the FEM model of the failure, shown in insert.](image)

### 1.3.2 Degradation and structural models

The objectives of work package 2 were to:

- identify and model important degradation phenomena and processes for selected railway assets for the purpose of LCC and LCA analysis.
- quantify the influence of intervention strategies on degradation time profiles.
- develop performance time profiles for selected asset types.
- validate the developed degradation and performance models through case studies.

At the start of the MAINLINE project, the available asset management tools for transport networks were largely deficient in the treatment of deterioration and how it impacts on Life Cycle Cost and Environmental Impact analysis. In particular, available models were hampered by simplifying assumptions made in deterioration models, which had been developed from limited laboratory (rather than field) data or simply transferred from allied, yet
distinct, industry sectors (e.g. corrosion models from the marine/offshore sector). This work package was aimed at the development and validation of deterioration models within a railway environment, in order to increase confidence in their predictions, which in turn would improve the capability of LCC estimates for alternative maintenance options.

Given the range and number of possible degradation mechanisms and asset types, research has been undertaken to devise an appropriate taxonomy which can be incorporated in an asset management tool. Thus, effort has been given to categorising degradation mechanisms bearing in mind the requirements of LCC and LCA calculations, and the need to cover assets with both relatively short and very long life-spans. The appropriate framework for performance, cost and environmental impact time profiles for different asset types under a range of degradation mechanisms has been a significant contribution towards the next generation asset management tools. In particular, we have:

- analysed the current models used for predicting the degradation typically found in elderly railway infrastructure to check if the results reflect observations.
- developed those models found to be deficient.
- created new models where no models currently exist.

The work first identified groups of railway assets, based on a ranking strategy that considered the potential to increase knowledge within the project's lifetime and the availability of field data for validation purposes. Additional considerations included the desire to cover asset types managed on the basis of their condition as well as those managed on a capacity basis, and the opportunity to demonstrate the development of deterioration models either from empirical data/observations or from physical laws and mechanical relationships (see Deliverable D2.1).

Particular attention was directed towards formulating the models so that they could be integrated within asset management tools that depend on both LCC and LCA algorithms. The modelling effort was complemented with targeted validation studies, which was carried out using knowledge and field experience from the participating consulting organisations and infrastructure managers. These activities led to improved and validated degradation and structural models, thus allowing infrastructure owners to examine and predict the performance of their assets with higher confidence. In turn, this led to more robust estimates of maintenance plans and budgets under a range of operational scenarios. Four distinct asset types, covering both condition and capacity related performance, were addressed: plain line track, soil cuttings, metallic bridges and concrete lined tunnels.

For all four asset types, available deterioration models were analysed and compared, and specific recommendations were made as to how they could be adapted for use in a railway context. Moreover, a number of improvements and insights were introduced in order to create complete and robust deterioration models (see Deliverable D2.2) that are compatible with the Life Cycle Cost methodology described in section 1.3.5. Specific examples of typical railway assets from each of the above four groups were presented in full, quantifying the influence of deterioration on the basis of changes in performance over time (see Deliverable D2.3). For plain line track and soil cuttings, the adopted approach was based on the analysis of large historical datasets pertaining to asset performance over a period of more than ten years. On the other hand, for metallic bridges and concrete lined tunnels, analytical modelling was preferred, partly based on test and field data but also relying to a considerable extent on physical understanding of the underlying deterioration mechanisms and structural behaviour. Finally, significant effort was directed towards scrutinising all the proposed models through comparisons with real data and targeted sensitivity analyses (see Deliverable D2.4).
The main outcomes from the activities related to degradation and structural models have been fed into the project methodology leading to integrated asset management tools. In this respect, an important research performance indicator was the readiness and user friendliness with which this task could be accomplished. The consortium has benefited from a broad spectrum of infrastructure owners and consultants, who were able to assess this aspect of the work directly and progressively during the project. In addition, the project advisory group, drawn from industry focused bodies directly involved with structure and track research and development, were able to assess the intrinsic quality and potential impact of the progress achieved with respect to the characterization of degradation mechanisms and their effect on structural models. The introduction of validated performance models for deteriorating assets into the LCAT tool is an important contribution to railway asset management practice, promoting the use of refined asset management strategies. With respect to wider dissemination, the outcomes from this activity have been presented at
international conferences (such as IABMAS etc) and will be submitted for publication in relevant scientific and technical journals. In this way, the outcomes have been subjected to wide peer review and professional scrutiny, which is based on quality, innovation, rigour and practicality.

To summarise, the main achievements are as follows:

- A deterioration model for Soil Cuttings which considers a number of time-invariant (such as soil type) and time-variant (such as vegetation and drainage) factors that predicts on the basis of historical trends captured through inspection cycles.
- A deterioration model for Track (Plain Line) that explicitly quantifies track quality as a function of time on the basis of initial conditions and a deterioration rate estimated considering line-specific factors (such as sleeper types, transport loads and track alignment).
- A deterioration model for metallic bridges susceptible to atmospheric pollution and corrosion, focusing first on the degradation of any available coating and the ensuing evolution of corrosion as coating becomes ineffective; the change of performance with time is captured under both condition criteria (such as percentage of unprotected area or fraction of thickness lost) and strength criteria (such as bending, shear or buckling capacity).
- A deterioration model for tunnels with concrete linings subject to chemical attack on reinforcing steel by carbon dioxide or by chloride ions, bearing in mind the specificities of tunnel geometry and availability of aggressive substances in a railway environment.

1.3.3 New construction techniques - Replacement of old infrastructure

Replacement is an important part when infrastructure assets have reached the end of their service life and are functionally obsolete. It should be carried out with minimum traffic disruption. Traffic disruption can be minimised through the clustering of different work items between the same closure points together, provided that there is no logistical clash between work sites. This can be achieved through careful preplanning. Work has been focussed on bridge structures and track systems as these are the infrastructure assets within the overall MAINLINE work plan that are most frequently replaced.

The objectives of work package 3 were:

- to investigate new construction methods and logistics for transport that minimize the time and cost required for the replacement of obsolete infrastructure. The focus here is on cost effective and environmentally sound methods that are easy to implement with low impact on the rail traffic and a short down time of the network.
- to plan and optimise the construction processes on existing lines where replacement of existing infrastructure is an alternative. Here the systematic approach is extremely important and should always be connected to LCCA. The results will help the infrastructure manager to decide for the most favourable measure from technical, social, environmental or cost demands.
- to deliver input regarding data to the development of life cycle cost models and other decision support systems for infrastructure managers. This includes taking into account construction time and logistics, short- and long-term impact on the network,
future maintenance issues but also environmental aspects such as emissions of greenhouse gases from temporary transport services.

A comparison of the techniques identified has been undertaken through detailed reviews to determine which are the most likely to offer benefit to the majority of railways in Europe. The most appropriate techniques discovered have been summarised in a series of guides analysing the advantages and disadvantages of each technique. These guides were supported by relevant case studies drawn from projects undertaken by the project partners or our international contacts.

Planning

A survey of railway infrastructure managers across Europe showed that, in those countries where there is a regime for compensating train operators when lines are not available to them, the longer notice of disruptive activities that is given the lower the compensation payment. In some cases lead times of several years are necessary when very long disruptive possessions are needed, even when these are usually only made available over the Easter and Christmas holiday periods. As a result, advice has been given on how to undertake long term planning by comparing the strategies and methods used across Europe. This could lead to a reduction of up to 60% in disruption costs.

Since not all countries have established regimes for charging disruption costs, a number of regimes were studied and a simplified method devised to assist those countries without a method. This will allow such countries to populate the relevant parts of the LCAT models with consistent data.

The survey also showed that the clustering of maintenance and renewal activities within disruptive possessions would lead to cost savings for individual projects as the disruption costs could be shared and productivity was likely to increase due to a higher efficiency of machinery use. An example quoted showed a productivity increase of 15% following the introduction of clustering.

Another important part of the planning process is the consideration of the environmental impact of the work proposed. The MAINLINE LCAT tool will be of assistance to this when looking in detail at individual construction activities but it is designed to deliver the impact in terms of CO₂ output or Euro equivalent. This means that other less easily quantified environmental impacts such as noise, which is becoming a more important issue in parts of Europe, are not addressed by the tool. Hence advice is given in D3.4 about how to reduce both the generation of noise and its export to neighbouring communities, with different solutions being offered for both bridgeworks and track works.

The application of the methodology of Reliability, Availability, Maintainability and Safety (RAMS) to new and existing structures has also been introduced by MAINLINE to the rail infrastructure sector.

Main focus is on the guidelines: MAINLINE has delivered “ready to use solutions” in the guideline for replacement of elderly infrastructure including

- state of the art,
- decision help for certain site conditions
- construction details, technical / engineering data to use the method developed or evaluated in MAINLINE.
Bridges

Most railway administrations across Europe have their own standard designs of bridges. A selection of these have been described and compared so that good or novel solutions from one railway can be adopted by others.

A Eurocode compliant design for a relatively simple concrete bridge, which could be considered as a future standard pan-European design, has been undertaken to compare the requirements of the Swedish and Spanish National Annexes. This has shown that there are only minor differences between the two designs and hence little practical difficulty in developing standardised products that could be offered commercially to the whole of Europe, with the potential for savings based on a larger scale of production.

The aim was not only to propose efficient methods to replace bridges but also to optimise procedures for different site situations. MAINLINE proposed and explained a project management system for infrastructure managers and also introduced strengths and weaknesses of different procurement processes. Installation methods also vary across Europe. The most popular method is by the use of either road or rail mounted cranes but this can lead to additional time and cost where lines are electrified as overhead equipment may need to be removed. To counteract this some countries possess special rail mounted bridge carriers and others rely more on multi wheel road based bridge carriers. In other cases replacement bridges are built alongside the existing bridge and then slid (or launched) laterally into position during a relatively short track closure. For long bridges, particularly over water, this method can be combined with the sequential longitudinal launching of individual spans constructed on dry land onto temporary supports prior to lateral movement. A table has been produced to compare the merits of each solution to assist infrastructure managers in the selection of the best option.
Finally, there are new techniques available to use prefabricated bridge units. They can be assembled on site and thus reduce the time for closure of rail traffic. MAINLINE has further developed these innovative methods and provided guidelines for how the assembly work can be performed in an efficient way. A special kind of bridge is the so called soil-steel bridge, which consists of a steel shell supported on a foundation and by soil backfill. This type of bridge, or culvert, is mostly used for small spans.
MAINLINE has explored the use of different installation techniques including open cut (trenched) and thrust boring & pipe jacking (trenchless) technologies. The use of novel materials for bridge construction, principally high performance concrete and fibre reinforced polymers (FRP), also known as advanced composites, has been investigated. This has shown that both materials have seen limited use worldwide in railway bridge applications and that they offer considerable promise in the future. Two notional designs have been produced:

- a replacement FRP deck on pre-existing metallic main girders which could produce weight savings of up to 50% when compared with the more traditional concrete alternative.
- a fully FRP composite railway bridge with a span capability of up to 50m which are expected to offer cost savings on both initial construction (due to their relative lightness) and through life (due to lower maintenance requirements).

Nevertheless the absence of a Eurocode covering the use of FRP material is likely to inhibit the take up of these solutions in the short term, although design guidance, without the formal status of codes, is available in a number of European countries.

![Figure 1-8 Example of bridge replacement methods](image-url)
Track

Track replacement falls into two distinct categories, plain line and switches and crossings (S&C), each of which has different logistical and engineering requirements. The total replacement of a complicated junction can take several days. Plain line can be done in short track possessions in order not to affect train operation but with very low output and high costs or on the contrary, the line can be closed during several weekends - or even weeks - depending on the line, available alternative routes and the country. The latter enables higher output and lower costs (see also LCAT). Therefore the length of track possession for track activities depends strongly on the requirements/demands of the IMs, which affects directly cost and output of the works.

Plain line renewal can vary from the use of manual labour with minimal assistance from plant such as cranes or excavators to the deployment of a modern fully automatic track relaying machine with the choice of system being dictated in part by the length of line to be replaced and the time available for the work. The manual method can be made less weather dependent by the use of mobile workshops (which can also be used when routine maintenance is undertaken) in which case the adjacent line can be kept open without restriction. The merits of each approach are discussed so that infrastructure managers can decide on the best approach for their own specific requirements. Major cost savings can usually only be achieved through the use of modern high output machines which have a high capital cost and thus need to be used intensively to justify the initial outlay.

Switch & crossing renewal, as outlined above, can vary from the replacement of a single lead turnout to the total replacement of a complicated junction. There are many methods available, ranging from hand build up on site to the transportation and installation of large components fabricated offsite. There are also a number of commercially available machines to assist the installation of S&C, such as the Automated Ballast Collector which efficiently removes the old ballast and compacts the subgrade to avoid future differential settlements.

It has been shown in INNOTRACK that there is a potential to improve replacement methods. This relates to two items, the first is to reduce replacement time, while the other is to assure track alignment and to reduce varying track stiffness. Starting from this MAINLINE has developed methods further to increase the quality of the work at site in order to make the switches and crossings last longer.

Figure 1-9 Different techniques for track renewal.

Switch & crossing renewal, as outlined above, can vary from the replacement of a single lead turnout to the total replacement of a complicated junction. There are many methods available, ranging from hand build up on site to the transportation and installation of large components fabricated offsite. There are also a number of commercially available machines to assist the installation of S&C, such as the Automated Ballast Collector which efficiently removes the old ballast and compacts the subgrade to avoid future differential settlements.

It has been shown in INNOTRACK that there is a potential to improve replacement methods. This relates to two items, the first is to reduce replacement time, while the other is to assure track alignment and to reduce varying track stiffness. Starting from this MAINLINE has developed methods further to increase the quality of the work at site in order to make the switches and crossings last longer.
Additionally the use of modular S&C is becoming more popular as it can give time savings of up to 80% and a 33% reduction in work force on site. All these options are discussed in detail in terms of required machinery, output and labour and compared in specially produced tables so that the most appropriate system can be chosen for each particular site. Moreover, additional recommendations are provided in order to achieve higher initial quality after the renewal (such as avoiding provisional clamping in favour of welding or always removing the complete layer of old ballast layer), which is essential to minimize future track degradation.

Comparisons have been undertaken between the use of under rail pads, under sleeper pads and under ballast mats for homogenising track stiffness through S&C, which is now believed to be an important factor in long term track behaviour. The results are presented in a series of graphs and the following conclusions drawn:

- soft rail pads are the most efficient system to minimize track stiffness variation and hence, impact load on the crossing, while under ballast mats have very little effect.
- the combined use of rail pads and under sleeper pads can bring additional benefits, and should be considered. However, the stiffness of rail pads and under sleeper pads should be revised if used together.
- further studies should be carried out on under sleeper pads.

It is well known that the use of wood sleepers in S&C improve the dynamic behaviour to a similar degree as the use of under sleeper pads. The disadvantage of wooden sleepers is that they need to be preserved to prevent rot using creosote, which is no longer environmentally acceptable. Hence the use of synthetic sleepers manufactured from fibre-reinforced foamed urethane (FFU) has been investigated. These are extensively used in Japan and have been used in a number of European countries. Whilst more expensive than comparative wooden sleepers, FFU sleepers should have a longer life (up to 50 years is suggested) so are likely to prove to be cheaper on a whole life cost basis.

Cleaning of ballast and exchange of sleepers is usually achieved through mechanised procedures. MAINLINE has examined and compared different methods to be able to propose further development and give guidance.

1.3.4 Monitoring and examination techniques

Monitoring and Examination (M&E) techniques are applied to assets so that timely action can be taken for these assets to remain fit for service. M&E systems thus form a crucial part of asset integrity management. They also provide valuable support in through life cycle management decision making by enabling asset managers to assess the remaining life of their assets and plan for life extension or decommissioning.

M&E systems range from the very basic visual inspection by trained personnel to the remotely operated real-time continuous monitoring systems employing electronics for sensing and wireless communication. The M&E techniques used must be compatible with other parts of the asset management system, particularly the degradation assessment models that necessarily require appropriate inputs from such techniques. The issues that MAINLINE has sought to investigate include state of the art M&E techniques and the interface between such techniques and degradation assessments.

The main objectives of work package 4 were to:

- clarify what inputs the degradation models require from advanced monitoring techniques and examination systems, investigate their use and identify how these can operate in the most cost-effective and reliable way to complement or replace existing examination techniques for elderly infrastructure. Such monitoring and
examination systems, together with the degradation models, are crucial for the effective and efficient integrated whole life asset management system described in section 1.3.5,

- provide case study/validation evidence so as to promote take-up of the proposed approaches by infrastructure managers.

The work package includes: assessment of currently used and promising M&E techniques, given the information provided regarding the degradation models in use; identification of gaps and recommendations to address the gaps between M&E and degradation assessment procedures; and, reports from Case Study applications.

The project has taken a broad, pragmatic view of the monitoring and examination requirements.

The main outcomes of WP4 are the three deliverables (D4.1-D4.3). These deliverables have provided:

- a realistic overview on currently available monitoring and examination techniques in relation to modelling the degradation process of railway assets,
- successful solutions to gaps in compatibility between monitoring and examination systems and degradation models,
- convincing validation of the improved methodologies via case studies.

The criteria and performance/research indicators that were used to measure the results, progress and impact of the project are as follows:

D4.1) Report on assessment of current monitoring and examination practices in relation to the degradation:

- The quality and comprehensiveness of assessment.
- Is the evaluation of monitoring and examination techniques sufficiently comprehensive to understand the efficiency and effectiveness of the methods in relation to their ability to provide input parameters for the degradation models?

Deliverable D4.1 provides an overview of currently available M&E techniques in relation to modelling degradation processes in a selection of railway assets – Cuttings, Metallic Bridges, Tunnels, Plain line, and Retaining Walls. This Deliverable summarises the pros and cons of each technique, draws on the suitability of these methods according to the degradation mechanism and the railway asset they apply to, and identifies gaps and issues to be addressed in the next stage in this work package.

D4.2) Solutions to gaps in compatibility between monitoring and examination systems and degradation models:

- Are the proposed solutions a step forward from the current state-of-the-art?
- Can the new approaches be used in practice? Have guidelines for practical use been developed? Will it be accepted and put into use by infrastructure managers?

Deliverable D4.2 is a report on the range of potential solutions to address the gaps identified in an efficient and cost-effective way. A suitable geographical coverage across Europe was ensured through the involvement of experts from both Western and Eastern European countries in the preparation of the document. A comparison of European best practice methods has been carried out to offer reliable conclusions in regard to solutions to compatibility gaps between monitoring and examination systems and degradation models.

D4.3) Report on case studies:

- Have at least two case studies and the relevant tests been completed?
- Do the case studies performed provide a convincing validation of the improved methodologies?
- Can the case studies performed contribute to the industry understanding of the proposed methodologies and help implement them into the practice of end users?

Deliverable D4.3 is a report on Case Studies showing the application of appropriate M&E techniques in the management of assets.

- Bridge Case Studies:

The Retszilas Bridge Case Study in Hungary illustrates how monitoring can be used to follow fatigue cracking and strengthening in a full scale test on a real bridge.

The Åby Bridge Case Study in Sweden illustrates how a photographic strain measurement system can be used. Results from the measurements are compared against traditional assessment of the remaining fatigue life of the bridge and finite element modelling.
These Case Studies have used information from the previous deliverables. In particular regarding fatigue in metallic bridges, optical sensors, photographic strain monitoring and full-scale testing are the proposed solutions to enable the measurement at points with maximum damage and calibrate fatigue models to improve their reliability.

- Earthworks Case Study:

Another Case Study is the Sligo Line Cutting in Ireland which is a SMARTRAIL test site too. The cutting is a live railway cutting on the Sligo line in North West Ireland, owned by Irish Rail. State-of-the-art M&E techniques and assessment procedures were used and results compared. This Case Study gained from the results from both MAINLINE and SMARTRAIL projects.

1.3.5 Whole life environmental and economic asset management

The continued growth in rail traffic across Europe will increase both the rate of deterioration of these railway assets and the need for shorter line closures for maintenance or renewal interventions. The impact of these interventions will need to take into account the financial constraints and enhanced environmental requirements as a result of new legislation. Tools to inform decision makers about the economic and environmental consequences of different intervention options are becoming essential to provide confidence and assurance.

The main objective of MAINLINE was to create a tool (Life Cycle Assessment Tool - LCAT) that can compare different maintenance/replacement strategies for track and infrastructure based on a life cycle evaluation quantifying:

- Direct economic costs
- Availability (Delay costs/user cost/benefit from upgrade etc.)
- Environmental impact costs
MAINLINE has gone further than the current state of the art on LCC and LCA for railway infrastructure assets through the setting up of databases for different asset types:

- including life-cycle performance, life-cycle cost and life-cycle environmental analysis;
- incorporating refined LCC and LCA formulae and supporting data inventories,
- sub-divided into parts that address renewal/replacement options and parts that address rehabilitation and strengthening options,
- for both parts, the databases are linked with improved degradation models, which includes possible interaction effects, and have the option of allowing the introduction of field data collected from rail assets,
- the databases also include data on costs and implementation aspects of inspection and monitoring techniques, so that their adoption can be evaluated in terms of LCC and LCA criteria.

MAINLINE’s activities have come together in the development of an asset management tool that combines LCA and LCC analysis in order to quantify and reduce environmental and cost impact for the renewal and maintenance of railway infrastructure using a holistic and properly validated methodology.

Emphasis has been given to both integration and transparency, so that the tool can be versatile and applicable to different scenarios across the European rail network. Methods for environmental impact normalisation and weighting have been presented and analysed through case studies. However, it is not the intention to combine both economic and environmental criteria through single score methods, to avoid narrowing down the scope of the tool, and to allow stakeholders from across Europe to exercise their judgement and expertise relevant to national/local conditions.

The initial work was to establish which existing asset management tools could be used for railway assets and whether they provide both life-cycle and environmental outputs. This analysis highlighted positive and negative features of existing software and also found that combining life-cycle and environmental outputs was uncommon.

Questionnaires were issued to Infrastructure Managers to confirm the extent and nature of any life-cycle assessment that was carried out within their organisations. The results varied across Europe, although some activity was carried out within all countries; and that environmental outputs were performed less frequently than life-cycle costing. The respondents recognised the growing importance of both environmental and life-cycle costing.

The LCAT models have been designed to bring together both the improved deterioration rates described in chapter 3 and the ability to use monitoring intervention and replacement techniques, described in chapters 4, 5 and 6 or from user experience.

LCAT models have been created for plain line track, metallic bridges and soil cuttings. These assets were selected due to interest from the infrastructure managers and availability of sufficient data to calculate deterioration rates. These three models have been written in Microsoft Excel to provide transparency and allow users to amend the models as they need in the future. A consistent layout and style has been used to give a common identity to the models.
The outputs from the LCAT are intended to assist the justification of interventions, to optimise spending of maintenance budgets, to compare different interventions and to predict the timing of future works and expenditure. Training workshops have been organised to discuss, explain and demonstrate the LCAT models to infrastructure managers and other users. This has also allowed the models to be refined, based on feedback from these sessions.

The examples below show the application of the LCAT for a metallic bridge and plain track. The metallic bridge is a single span structure with half-through girders and is a typical railway asset. The inputs to the LCAT describe the properties of an individual element of the bridge, its dimensions and acceptable limits for both condition and loss of section which determines the strength in terms of shear and bending. The LCAT uses these limits, together with any defined maximum intervals for specific interventions. These limits are applied to the degradation rates within the LCAT and a life-cycle plan is generated, as shown in Figure 1-14. It shows the financial and environmental costs relating to the physical works, and coating and section loss over time.

Figure 1-12 Examples of areas where LCAT is developed today.
The track example is for a length of route with good drainage and formation that is used by freight. Acceptable quality limits (Q) have been defined by the user to trigger interventions for tamping of the ballast and also relaying the track. Again, the degradation rates within the LCAT create the life-cycle plan shown in Figure 1-15.
1.4 Potential impact

The MAINLINE project has targeted a reduced environmental footprint for selected items of rail infrastructure in terms of embodied carbon and other environmental benefits. The project has:

- Improved degradation and asset modelling to develop more realistic life cycle assessment to establish environmental impact of the proposed intervention works.
- Investigated monitoring techniques to compliment or replace existing examination techniques, reducing the need for construction works.
- Applied new technologies to extend the life of elderly infrastructure
- Investigated new construction methods for the replacement of obsolete infrastructure
- Developed decision support tools to assess whole life environmental and economic impact.

1.4.1 Major impacts

Economic Impact

Many Infrastructure Managers do not yet use Life Cycle Costing (i.e. financial) and/or Life Cycle Assessment (i.e. environmental) in the planning of maintenance and renewal of their rail infrastructure. There is a lack of data and methods and here the MAINLINE project gives guidance. There is also often a lack of economic resources for maintenance which may lead to a shorter service life and less sustainability than would otherwise be the case; results from the MAINLINE Project give advice that may help to improve this situation. The Life Cycle Assessment Tools (LCAT) have been developed which allow users to demonstrate optimum interventions and reduced capital expenditure.

Europe has a railway network of some 230,000 km with an asset value of more than 1500 billion € and is spending – with large variations – less than 1% of it for yearly maintenance, UIC (2006, 2010). A large proportion of the civil engineering structures and tracks are old: of the 500,000 bridges, 35 % are over 100 years old and earthworks and tunnels are often older. Nonetheless they can, with the help of the outcomes from the MAINLINE project, safely remain in service for longer periods than currently anticipated, improving the ability of the railways to deliver increased mobility across Europe and play an increasingly important role in the development of integrated, safer, “greener” and “smarter” pan-European transport systems.

The results from the MAINLINE project will facilitate longer service lives for existing railway infrastructure, which will bring about great savings for rail administrations in Europe. This will be done by providing improved life extension methods (WP1), understanding of infrastructure degradation (WP2) and enhanced monitoring and examination techniques (WP4). MAINLINE has also provided methods to optimize replacement of obsolete structures (WP3), and developed a tool for evaluating all these options (WP5), in a transparent economic cost and environmental impact framework. A modest 10 year increase in the service life of 2% of the bridges due to the outputs from the MAINLINE project implies that the replacement of 10,000 bridges could be postponed for 10 years with notional cost savings calculated below.

- The average construction cost (K) of a new railway bridges is about 1M €.
- With a low interest rate (p) of 2% the present value of the cost for a rebuilding a bridge in 10 years will be \( K/(1+p)^{10} = 0.820 \times K \).

---

• The saving compared to rebuilding the bridge now will then be $K - 0.820 K = 0.180 K$.
• Not replacing 1,000 bridges per year gives a saving of $1,000 \times 0.180 \times 1 \text{ M€} = 180 \text{ M€}$.

Similar savings will be available for other kinds of infrastructure; for instance in INNOTRACK significant performance enhancements for Switches and Crossings (S&C) were developed and demonstrated. Follow up in 2013, 4 years after INNOTRACK, proved LCC savings in order of 20% for the four demonstrated S&C. MAINLINE also showed that there is potential to enhance replacement methods of S&C by reducing replacement time, ensuring good track alignment and reducing varying track stiffness.

Additional savings have arisen from the MAINLINE results for plain line track and soil cuttings.

The combined impact will thus be an effective and efficient improvement of infrastructure based on whole life considerations. The impact will be especially important in considering the improvement of combined rail freight and passenger networks that require substantial infrastructure upgrading, as is the case within Eastern Europe and developing economies.

Environmental Impact

Traditionally the main environmental consideration associated with railway operation has been related to reducing noise and vibration, but with the main environmental focus now turning to climate change and the associated carbon agenda new considerations are becoming important. In common with many other parts of the built environment the carbon impact of railway infrastructure is dominated by usage rather than initial construction or ongoing maintenance. In this respect, the railway is already very favourable with emissions of the order of 50 g CO$_2$/passenger km compared to road and air transportation with double or triple values, Network Rail (2010)$^3$ However if the railway industry is to play its part in meeting the carbon reduction targets set within Europe then the carbon impact of infrastructure maintenance and renewal activities will have to decrease.

Within the MAINLINE project a tool has been developed that enables railway administrations to assess the environmental (carbon) impact of various maintenance or renewal interventions under consideration and hence have the opportunity to select the one with the least impact. Unfortunately, the current state of knowledge about the carbon impact of typical interventions is limited, which means that it is difficult to quantify the benefits from the project. However the example below gives an indication of the kind of benefits that could be realised:

• The emission of carbon dioxide from the building of a concrete bridge containing 160 m$^3$ of concrete can be calculated in the following way.

  • 1 m$^3$ of concrete weighs approximately 2.3 tonnes.
    - Concrete contains about 400 kg of cement per tonne
    - Cement production creates approximately 700 kg CO$_2$/tonne
    - This gives $160 \times 2.3 \times 0.4 \times 0.7 \text{ ton} = 103 \text{ tonnes CO}_2$.

  • Add to this we add 150 kg reinforcement steel per m$^3$ of concrete.
    - Steel production is responsible for some 1.2 kg CO$_2$/kg steel
    - This gives $160 \times 0.15 \times 1.2 \text{ tonne} = 29 \text{ tonnes CO}_2$.

  • In total, estimated emissions are $103 + 29 \approx 130 \text{ tonnes CO}_2$ per new bridge.

Research projects developing a new generation of lightweight, low energy, self-compacting concretes for structural applications has shown that it is possible to replace substantial quantities of cement with PFA (pulverised fuel ash) or GGBS (ground granulated blast furnace slag) without affecting structural performance. This can save around 40% of the embedded energy in concrete (Owens 2010), which would mean a reduction of 40 tonnes CO$_2$ from the concrete – equivalent to a 30% reduction in overall carbon footprint for such a bridge.

The potential for savings in a new build scenario can be demonstrated by reference to the Environment Product Declaration prepared for 190 km of a new single track railway with 90 bridges of a total length of 11 km and with 25 km of tunnels, Bothniabanan (2010). In a per km analysis, the bridges were calculated to emit 8 050 ton CO$_2$ equivalents and use 22 GWh (80 TJ) during construction and 60 years of maintenance. The energy use per km of tunnel was of the same magnitude but the emission was about half of that of the bridges. On a per bridge basis, this gives, on average, an emission of 1020 ton CO$_2$ equivalents and a use of energy of 2,65 GWh (9,5 TJ). So the savings in extending the life of existing structures instead of replacing them are large.

Impact on excellence of European research

Railway lines cross National borders in Europe so the infrastructure ought to be analysed in the same way on the different sides of these borders, particularly as the basic infrastructure types are similar. Hence it is advantageous to study them together as today most countries are too small to support this kind of endeavour in isolation.

By carrying out a project such as MAINLINE together it will be easier to implement its results in the different states of Europe. By co-operating on a European level it is also possible to share resources and reach a result in a shorter time, which is necessary in order to meet the demands on the railways, and at a significantly lower overall cost. Additionally, good practice can be promulgated more easily and effectively to achieve the best benefits from project outputs.

Research partners from all over Europe get increasingly more connected through different projects. Their special fields of expertise are well known and collaboration between Scandinavian and Iberian partners and/or UK institutes has been going on for some years. Working together, exchanging ideas and solutions to solve actual problems for end users is an effective way to exchange knowledge. As research has become an internationally competitive field, this joint project has helped European research in an international context. The universities and research institutes have benefited from direct contact with end users. Problems have been discussed and the importance attached by end users to economic issues has been better appreciated. Additionally, the growing importance of environmental impact has been considered jointly, thus promoting consensus and common understanding of future constraints.

The collaboration in this project has helped promote market ready solutions - this is a very effective way to sell European expertise, and researchers/practitioners have been able to establish contacts with European industries and end users outside their normal working locations. Language problems still exist for railway maintenance personnel, however, by increased collaboration this may be reduced and finally overcome with better educated younger personnel. Future contacts with experts from other countries will be facilitated and collaboration will be enhanced, especially the contact between Eastern and Western European Universities will be facilitated.
Steps needed to bring about these impacts

Project results need to be implemented by the railway owners in their infrastructure management systems. Recently technical developments in earlier projects, such as Sustainable Bridges, INNOTRACK and Urban Track have been introduced successfully in many railways and the new ideas of life time extension and LCC developed by the MAINLINE project have been disseminated. However, more examples and tests are needed to show how life cycle methods and effective maintenance planning can work together. This will, in time, increase the understanding and popularity of these methods. As this is a novel way of planning and managing the maintenance of railway infrastructure no guidelines, rules or standards exist, hence railway administrations themselves might have difficulties in testing and adopting the methodology. However, MAINLINE has undertaken the basic research and development activities and produced guidelines for everyday use. In this way the end users can rely on the results and the acceptability of the methods will be higher. Acceptability will be enhanced if it can be shown that the savings that can be made by extending the lifetime of infrastructure components have no negative influence on the safety. The real life use of the MAINLINE LCAT by project partners, which is expected to take place in the near future, coupled with further research into degradation models and the subsequent development of LCATs for other asset types can effectively strengthen this position and the acceptability of the methods will be enhanced considerably.

A second step is the dissemination throughout the rail organizations of the methods developed in both this and earlier projects, and a third step is the full scale use of them. Examples need again to be presented in UIC workshops and at railway conferences. More data will then be available and the methods can be further refined. Looking at the spending on infrastructure in general, the LCC method will become more and more important for all parts of the society. The political discussion will help to involve infrastructure managers and economists to consider life time extensions.

European dimension

When MAINLINE started, FP7 was the most suitable programme to support an international research collaboration of public and private partners at the European level. It defined a framework for collaboration (contractual framework, role and responsibility of the partners, IPR rules, centrally defined financial regime, project review and reporting methodology, etc.) that facilitated the organisation of international RTD collaborations which would be difficult to set up outside of the European RTD Programmes. Moreover MAINLINE also benefited from the connections between researchers and industries that were made in earlier joint European research activities. Of particular importance to the MAINLINE project was co-operation with its sister FP7 project SMARTRAIL, where data and expertise was shared in a very constructive way.

The consortium consisted of railways partners from all over Europe. All of them have collaborations with neighbouring countries and a direct interest in good co-operation with them. In this way MAINLINE could benefit from many other European and nationally funded projects that all of them were involved in. Indeed, the MAINLINE consortium was carefully selected to include MAV (the Hungarian railway) and TCCD (the Turkish railway) as active members in this project. They have brought not only their own expertise but also a view from the eastern part of Europe and have been well placed to promote dissemination and exploitation of the MAINLINE results. For example, MAV have very good operational and research activities connected to the former Russian Federation and Eastern European areas. Their solutions and strategies are very interesting and valuable for new research activities in the field of maintenance. On the one hand the project will benefit from this knowledge and on the other hand dissemination of project results will be very much easier having partners of known expertise to spread this information in existing working groups.
The MAINLINE partners has benefited from, and built upon, existing knowledge acquired in previous and on-going European, international and national projects. The liaison was ensured by the MAINLINE partners involved in these projects or having ongoing collaborations with the coordinators of these projects. This liaison avoided unnecessary duplication and ensured that MAINLINE was well placed to make use of any emerging results, so allowing MAINLINE to meet its objectives in the most efficient and effective way.

1.4.2 Dissemination activities and exploitation of results

Dissemination

The dissemination and communication about the project and its findings to the relevant target audiences is crucial for the success of the project. An information dissemination plan was set up at the start of the project, which detailed the project dissemination and communication activities, their objectives, targets, tools and associated budget. The objectives of the MAINLINE dissemination and communication activities have been to:

- implement the dissemination plan by ensuring effective communication at all levels and by providing appropriately targeted information to all identified audiences;
- ensure liaison with stakeholders;
- ensure visibility of the results obtained and make available information relevant for further application;
- exchange the knowledge with the scientific community in order to obtain new insights to be integrated into the project research;
- foster synergies and complementarities with other relevant EU, and national and international programmes and projects;
- ensure that rail sector stakeholders and the general public appreciate the added value of EU support and how it contributes to a cost effective, well maintained rail infrastructure.

More precisely, MAINLINE has held three workshops:

- Midterm workshop at UIC in Paris, 14-15 May 2013, to identify common fields of interest with the SMARTRAIL project, funded by FP7 under the same theme
- Workshop targeted to Central and Eastern Europe, Budapest, 15 May 2014, to disseminate knowledge and results to Central and Eastern Europe
- Final workshop at UIC in Paris, 30 September 2014, to present and distribute final project results: LCAT tools, guidelines and other reports

The project also undertook a two-step training programme on the use of the Life Cycle Assessment Tool (LCAT) to present and distribute the LCAT tools developed in MAINLINE, together with the user manual.

In addition, MAINLINE partners have made presentations in many national and international events. The most comprehensive presentation was a Mini Symposium held as part of the IABMAS (International Association for Bridge Management and Safety) 2014 Conference, held in Shanghai on 7-10 July 2014, where 8 papers were presented.

Finally, MAINLINE has produced many deliverables, most of which are public and available on the project website: http://www.mainline-project.eu. The consortium also published several press releases through UIC, all available on the public website as well. Some partners have also published articles in national journals, notably in Sweden, Denmark and Hungary.
The results have been presented to established international working groups throughout the project. Future exploitation of the results is expected to continue after the project ends through the creation of new working groups supported by the relevant project partners, probably under the overall umbrella of UIC. By working with established UIC groups like TEG (Track Expert Group) and PoSE (Panel of Structural Experts), MAINLINE has also reached standardisation bodies.

In addition MAINLINE has worked together with the European sister project SMARTRAIL including arrangement of a common workshop, technical meetings and exchange of documents.

Exploitation

Project partners will ensure that MAINLINE continues to develop after project finalisation. Universities and research institutes will continue their research into key issues which have been identified as important for further investigation and have the potential for providing tools or methods to improve sustainability and cost effective solutions for railway infrastructure. Examples of issues relevant for further research are:

- Identification of track condition taking into account other maintenance activities
- Strengthening and assessment of bridges
- Deterioration of tunnels
- Strengthening of earthworks

UIC has and will spread the results among its members mainly through two expert groups namely Track Expert Group (TEG) and Panel of Structural Experts (PoSE). On several occasions, this has been carried out during the MAINLINE project. Also a working group has been proposed to continue the development of the LCAT under the UIC umbrella.

Railway infrastructure managers which have been part of the project will continue to exploit the outcome within their own organisation. MAV has translated selected deliverables into Hungarian in order to maximise the exploitation of the MAINLINE results. It is expected that the railway infrastructure managers will be able to include relevant parts of the guidelines into national good practise and that the Life Cycle Assessment Tool (LCAT) can be further developed and customised to fulfil the requirements of different infrastructure managers. Is has been a key issue for the project that the tool has been developed in Excel and the programming is open for further customisation.

The industrial partners will continue to exploit the guidelines and the tools within their organisation and by including the results into their services. Thereby consultants and contractors can provide assistance to disseminate and exploit the results to railway infrastructure managers who have not participated in the project.

The life-cycle approach developed within the project and the principles of the LCAT will be used by Cerema (formerly SETRA) to the development of a new bridge management system (for road bridges) in France. Consequently the work performed within the railway infrastructure field will be extended to cover road infrastructure as well.

TWI is a research and technology organisation that has a membership base of more than 700 members across the globe and in a variety of industry sectors. Thus, it is in a position to disseminate and adapt the results from MAINLINE to a number of industrial situations. TWI identifies the combination of Life Cycle Costs (LCC) and Life Cycle Assessments (LCA) as a
key area to develop expertise in. TWI has sponsored a research project in this area and is looking for other opportunities to build on the achievements of MAINLINE.

1.5 MAINLINE Partners and Contact

MAINLINE Coordinator

MAINLINE public reports, including guidelines and tools

The intention of the MAINLINE project was that the core part of the results is public, this is why the most important deliverables, as well as the tools developed as main result, are freely accessible on MAINLINE public website. MAINLINE reports will be useful especially for Infrastructure Managers (IMs), but also to researchers, professors and students in universities in the years to come as they provide thorough analyses of methods and tools of infrastructure management and life cycle assessment (LCA). The guidelines provide a reference framework for decisions of IMs and the tools a basis for calculations and LCA, which can be used by IMs directly or further developed by consulting companies. The expected impact would be that IMs tend to use this kind of tools and approach more and more often.

MAINLINE Life Cycle Assessment Tools (LCATs)

It is expected that the presentation of the LCAT to Infrastructure Managers will make way for the use of the tool in the industry. COWI and Jacobs/SKM will be able to help IMs to tailor the tool to the actual business especially considering bridges, tunnels and cuttings. In this way the IMs can benefit from more cost-optimal management of railway or road infrastructure – including considerations of environmental impact. Concerning COWI, the presentations can e.g. take place at annual meetings with COWI's customers and other infrastructure meetings like Danish Bridge Day or Danish Repair Day. The presenters will be key staff from COWI who have participated in MAINLINE. Jacobs/SKM will use the outputs from MAINLINE to assist asset owners to further develop and update their current models.

MAINLINE guidelines

UIC will contribute to make sure that project results become part of best practise within European and international codes, standards and guidelines in the next years. In Denmark, COWI is active in the preparation of national codes and standards. In this context they will benefit from new best practice presented in the MAINLINE guidelines. COWI will when relevant include the MAINLINE work in e.g. national annexes to Eurocodes or other infrastructure standards. The contributors from COWI will be key staff who have participated in MAINLINE. In this way all the progress within maintenance, renewal and improvement provided by the guidelines will be implemented in Danish codes and best practice.

LCAT methodology/tools

The results will be used in the education and training of students in basic and advanced courses, as well as in workshops and seminars, starting from the current academic year. For Surrey for example, relevant project outcomes will be fed into teaching programmes, in particular its Master’s courses. The LCAT tools developed for Bridges and Cuttings will be used by post-graduate students attending the MSc programmes in Bridge or Civil Engineering, and in the newly launched programmes on Infrastructure Engineering and Management.

Benchmarking of degradation profiles

Infrastructure Managers use modelling to show the future condition/risk profile of their assets which typically forms part of the funding requests from central government. The degradation profiles generated by MAINLINE will provide a benchmark against rates already used by
the Infrastructure Managers, helping to validate assumptions made in their funding requests in the years to come. The degradation profiles could also be used by other parties who are creating their own life-cycle models. The MAINLINE degradation profiles provide a good base, but further research/updates will allow them to be continuously refined and possibly to include further material types.
3. Societal Implications

The report covering the wider societal implications of the project, in the form of a questionnaire, including where applicable gender equality actions, ethical issues, efforts to involve other actors and to spread awareness has been answered online.
