Objective

Mercury (Hg) is a pollutant of global concern for human and ecosystem health. This is particularly true in the Arctic where indigenous populations are excessively exposed to dietary Hg from fish and marine mammal consumption. The deposition of Hg from the atmosphere to Earth surfaces and its re-emission via biogeochemical

reduction processes determine Hg concentrations in Earth surface reservoirs, such as soils, snow, and runoff into Arctic lakes and surface Ocean. In order to predict the impact of anthropogenic Hg emissions on net atmospheric Hg deposition and ultimately Hg concentrations in biota, it is important to understand these deposition and re-emission processes. The reduction of deposited Hg²⁺ to volatile gaseous Hg⁰ and the oxidation of gaseous Hg⁰ to reactive Hg²⁺, which is rapidly deposited from the atmosphere, control the global fate of Hg. Major knowledge gaps concerning the mechanisms of these redox processes exist.

Different photochemical and non-photochemical Hg²⁺ reduction mechanisms were found to fractionate Hg stable isotopes in distinct, identifiable ways. Also, different atmospheric Hg⁰ and Hg²⁺ pools have been shown to have distinguishable Hg isotope signatures. Hg isotopes can thus provide new insights in the sources of Hg and redox transformation processes at the Earth-atmosphere interface, which are inaccessible by means of concentration and flux measurements alone. In the MEROXRE project proposed here we will combine the latest innovations in gaseous Hg measurements in porous media (soils, snow) with state-of-the-art Hg isotope techniques to investigate:

- (i) Hg isotope fractionation of Hg²⁺ reduction and gaseous Hg⁰ oxidation in interstitial snow air and soil pores.
- (ii) Hg isotope fractionation factors associated with net gaseous Hg⁰ re-emission fluxes from soil and snow
- (iii) the importance of gaseous Hg⁰ oxidation and Hg²⁺ reduction and re-emission for the global Hg cycle by incorporating the results in a global Hg isotope model.
